Detection of antibiotic resistances in microorganisms

Description

- 5 The invention relates to a process for detecting antibiotic resistance in microorganisms, in particular in bacteria, and to reagent kits which are suitable for implementing the process.
- Zuckerkandel and Pauling (1965) who, in the article: 10 "Molecules as documents of evolutionary history" were the first to point out the possibility of revealing the evolution of organisms by comparing the sequences of their appurtenant macromolecules, laid the foundation developing an rRNA-directed in-situ 15 stone for hybridization for detecting pathogenic organisms. was then Carl Woese who used this concept for working first natural classification prokaryotes (Woese, 1987). A further result of these investigations was that rRNA sequences exhibit so-20 called signature sequences which are typical particular domains, phyla, families, genera and even individual species. Detecting these signature sequences with the aid of PCR primers or hybridization probes 25 therefore makes it possible to identify bacteria on different taxonomic levels. In addition, the high number of rRNA molecules which are naturally present in the bacterial cell (10^4-10^5) in rapidly growing bacteria) increases the sensitivity of the method and made it possible to use in-situ hybridization techniques which 30 employ rRNA as the target molecule. Using radioactively labeled oligonucleotide probes, Giovannoni et al. 1988 were the first to be able to detect rRNA in whole
- bacterial cells and, one year later, DeLong et al.
- (1989) carried out such an in-situ hybridization using 35 fluorescence-labeled oligonucleotides.

Recently, this technique has been employed frequently, particularly in environmental microbiology. The location of particular physiological groups (Wagner et al., 1993; Ramsing et al., 1993) and the influence of particular agents on the composition of the population of an ecosystem (Wagner et al., 1995) were the focus of interest in this connection.

However, this technique has also been employed successfully for detecting bacteria in the food hygiene sphere (Beimfohr et al., 1993). Medical microbiology is another field of microbiology in which rRNA-directed whole-cell hybridization is applied.

- Thus, H. influenzae has been detected in throat swabs taken from children (Forsgren et al., 1994), Candida species have been detected in blood cultures and tissue samples taken from artificially infected animals (Lischewski et al., 1996, Lischewski et al., 1997),
- pathogenic Yersinia species have been detected in tissue sections, stools and throat swab samples (Trebesius et al., 1998), and salmonella have been hybridized as successfully in swabs (Nordentoftet al., 1997) as have bifidobacteria in stool samples

25 (Langendijk et al., 1995).

As various investigations have demonstrated, the number of ribosomes in rapidly growing, heterotrophic bacteria depends heavily on the growth rate and physiological activity of the organism (Schaechter et 30 1958). Since the quantity of bound probe proportional to the quantity of rRNA, the state of growth of a cell can also be determined indirectly by way of the hybridization-mediated fluorescence (DeLong et al., 1989). 35

A comparison of the translation apparatus in eukaryotic cells and in bacterial cells shows considerable

differences in the function and structure of individual components. These differences create therapeutic window for a series of active compounds intervene specifically in the bacterial which translation process but which do not intervene in the Table 1 translation process. eukaryotic frequently employed antibiotics which intervene in the translation process in the bacterial cell. These active compounds possess the second highest worldwide market share, coming after the antibiotics which are directed 10 against peptidoglycans.

However, the massive therapeutic employment of these substances leads to the emergence of resistances in clinical isolates and consequently to therapy failures. A number of causes may be responsible for the appearance of such a mutation:

- (1) Change in the target site for the antibiotic
- 20 (2) Modification of the antibiotic
 - (3) Change in the transport of the antibiotic

In of the MLS antibiotics (macrolide, the case lincosamide, streptogramin B), which achieve their 25 effect by blockading the ribosomal peptidyltransferase center, investigations carried out on clinical isolates lead to the conclusion that changes in the target site for the antibiotic are responsible for the development of resistance in the overwhelming majority of cases 30 (Versalovic et al., 1997). Several variants are also conceivable in this connection.

- (1) Mutation of ribosomal proteins
- (2) Mutation of the rRNA
- 35 (3) Posttranscriptional modification

Whereas it was generally assumed previously that change in ribosomal proteins was mainly responsible for the

development of resistance, experimental data of more recent origin militate against such a theory and instead support the thesis that changes which take place directly on the ribosomal RNA (posttranscriptional methylation or mutation) lead to the development of resistance.

Table 1:

Class/Active compound	Use
Aminoglycoside/aminocyclitol	Market share: 3%
antibiotics	Tuberculosis therapy;
(Dihyro)streptomycin	resistance frequent
neomycin, paromomycin	oral and topical use
kanamycin	parenteral administration;
gentamicin, tobramycin,	resistance frequent
amikacin, netilmicin,	new; broad spectrum (not
sisomicin	Streptococci or Enterococci;
	ototoxic and nephrotoxic;
spectinomycin	blood level control)
	penicillinase-resistant
	gonococci
Lincosamides	
Lincomycin, clindamycin	Gram-positive bacteria and
	Gram-negative anaerobes; good
	penetration into bone tissue;
	in the case of toxin formers
Macrolides	Market share: 11%
Erythromycin, roxithromycin,	Against Gram-positive and
clarithromycin, Azithromycin	Gram-negative cocci,
	chlamydias and mycoplasmas,
	Helicobacter; good ability to
	traverse the membrane \rightarrow
	intracellular bacteria
Tetracyclines	Market share: 3.5%
Tetracycline,	Broad spectrum, including
oxytetracycline,	chlamydias and rickettsias;
rolitetracycline,	predominantly bacteriostatic;
doxycycline, minocycline	resistance frequent;
	deposition on teeth in
	infants;

10 Thus, carbomycin was able to inhibit the in-vitro peptidyltransferase activity which was exhibited by protein-free 23S rRNA extracts (Noller et al., 1992). Furthermore, the affinity constants for the binding

15

between erythromycin and ribosomal proteins, such as L15, which are claimed to be potential candidates for the appearance of resistance, are several orders of size less than those which were ascertained for complete ribosomes (Weisblum, 1995). In particular, however, the lack of erythromycin-resistant clinical isolates which have a mutation in their ribosomal proteins indicates that this mechanism of resistance is more likely to be of little importance (Weisblum, 1995).

However, the other two mechanisms of resistance are frequently encountered, with a striking observation being that the target region for both changes relate [sic] to particular bases in domain V of the 23S rRNA (Brimacombe, 1990).

An adenine residue in E.coli position 2058 (numbering

according to Brosius et al., 1981), which residue is 20 located in the tertiary structure of the 23S rRNA between helices 73 and 74 (numbering according to Brimacombe et al., 1980), is the substrate for the modification by methylases of the erm family which have been isolated from various macrolide-resistant clinical isolates (Weisblum, 1995). An $A \rightarrow G$ transition in this 25 position also leads to a resistance phenotype in a of phylogenetically dissimilar bacteria (Mycobacterium intracellulare (Meier et al., H. pylori (Versalovic et al., 1997), E.coli (Sigmund et 30 al., 1988, Vester and Garrett, 1987), Propionibacterium acnes (Ross et al., 1997) and Mycoplasma pneumoniae (Lucier et al. 1995). Table 2 lists a number of other mutations in the peptidyltransferase center of the 23S rRNA which are found in resistant bacteria. 35 conserved nature of the positions which lead to MLS resistance, and their discovery in a very wide variety phylogenetic groups (not only bacteria), demonstrates the general nature of this phenomenon.

Since the discovery of these mutations is relatively is to be expected recent, it modifications/mutations of the rRNA/rDNA will be positively identified in the coming years as being the cause of resistance development in a number of other clinical isolates. Experimental evidence pointing to this already exists in the case of the Mollicutes (Mycoplasma and Ureaplasma) (Palu et al., 1989, Stopler and Branski, 1986), for which MLS antibiotics are also the therapeutic agents of choice.

Table 2:

10

Mutation	Species	Phenotype
G2057A	P.acnes	Cla ^R , Ery ^R
A2058G	P.acnes	Cla ^R , Ery ^R
A2059G	P.acnes	Cla ^R , Ery ^R

Table modified in accordance with the Weisblum, 1995, reference. Cam, chloramphenicol, Cla, clarithromycin, Cln, clindamycin, Ery, erythromycin, Lin, lincomycin,

Sgb, streptogramin type B. HS, hypersensitive; R, resistant; S, sensitive.

the increasing number of antibiotic resistances in clinically relevant bacteria, the rapid identification of resistant bacteria is assuming ever greater importance. The number of pathogenic bacterial resistant to species which are at therapeutically important antibiotic is continually increasing. In view of this situation, it is only 10 possible to implement an effective therapy when the resistance status of the pathogenic organism is known. The methods for determining the resistance status of bacteria which are generally practised are essentially based on time-consuming growth tests which investigate 15 the efficacy of the antibiotics which can be employed therapeutically. To this end, the bacteria have, as a rule, to be cultured twice, a procedure which lasts approx. 48 hours. The investigation of slowly growing organisms lasts correspondingly longer. According to 20 the current state of the art, therefore, a highly effective therapy can only be initiated after a time delay of at least 1 to 2 days.

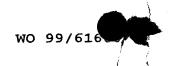

solving the problem of rapidly 25 to approach identifying antibiotic resistances in bacteria, particular in the case of those antibiotics which are directed against the translation apparatus of microorganisms, is that of improving the method of in-situ hybridization for detecting point mutations. 30 The components of the translation apparatus are present large number of copies in a cell and consequently be investigated directly, i.e. without any additional amplification step. The rRNA, according to more recent findings, is 35 involved in expressing antibiotic resistances and can consequently be employed as an indicator, particular interest in this connection.

15

20

25

30

the remarks which follow, the procedure developing probes for determining antibiotic resistance is described using the clinically important bacterium Helicobacter pylori as an example, while the essential components of appropriate test kits are also indicated examples. An appropriate means of determining resistance can then be derived for each clinically relevant bacterium and each therapeutically relevant antibiotic using these guidelines.

The development of antibiotic resistances as a result of mutations in ribosomal nucleic acid sequences also consequences for treating Helicobacter infections. While the occurrence of spiral bacteria in the mucous membrane of the human stomach has been reported since the beginning of this 1893), the fact that the organisms were (Bizzozero, pathogenic was only realized, and scientifically acknowledged, when Marshall and Warren (Warren Marshall, 1983; Marshall et al., 1984) successfully isolated and cultured this bacterium from the mucous membrane of the stomach of a patient suffering from a gastric ulcer (ulcus ventriculi). As the first analyses showed, the isolated microorganisms were Gram-negative, bacteria which were extremely mobile spiral possessed the unusual ability to survive in strongly acid medium (up to approx. pH 1). Originally designated Campylobacter pylori, the organisms were finally the basis of their biochemical grouped, on morphological properties, in the newly established genus "Helicobacter" (Goodwin et al., 1989).

In 1987, Dent and coworkers were the first to identify a corkscrew-like organism in the mucous membrane of the human stomach and to designate it "Gastrospirillum hominis". Since such a bacterium has so far only been successfully cultured in exceptional cases, assignment

10

15

20

to this "species" is made on the basis of location in the mucous membrane of the human antrum and of cell morphology (rod which is wound in a corkscrew-like manner). In 1993, Solnick and coworkers determined the 16S rRNA sequence of two "Gastrospirillum hominis" rods and established that this bacterium had to be assigned to the genus "Helicobacter". They consequently proposed the name "Helicobacter heilmannii". It already became clear in this investigation that it did not in fact appear justified to bring these two strains together under the umbrella of one species since the difference in the 16S rRNA sequence was more than 3.5% (it is arte legis to regard two isolates as being different species from 3% onwards), whereas the difference between one of the strains (Gh2) and Helicobacter felis was only 1.5%. A H.heilmannii which it was possible to culture was described by Holck et al. 1997. However, sequencing data showed that this organism is more closely related to the newly described Helicobacter salomonis than it is to the H.heilmannii described by Solnick.

"Helicobacter heilmanii" (formerly "Gastrospirillum hominis") is therefore a phylogenetically heterogeneous group of Helicobacter species which are rarely found in the mucous membrane of the human stomach but which are, precisely like H.pylori, causatively involved, inter alia, in the development of gastric ulcers (Yeomans et al., 1996). Assignment to this group is made on the basis of morphological criteria (large rods which are wound in a corkscrew-like manner).

The importance of Helicobacter infection, and the consequence of this discovery, became clear within a few years. Epidemiological investigations carried out by Taylor and Blaser (1991) showed that Helicobacter infection occurs worldwide and that approx. 50% of the population are infected with these bacteria, with the infection rate being higher in developing countries

than in industrialized countries. Another observation is that the probability of a chronic infection with Helicobacter increases drastically with increasing age. As a consequence, Helicobacter infections are among the most frequently occurring chronic bacterial infections in humans.

Ιt nowadays known that infection in inevitably leads to the triggering of a bacterial 10 gastritis (type B gastritis). Ιt is furthermore having been proved that accepted as Helicobacter also play a causative role in infections development of gastric and duodenal ulcers (ulcus ventriculi and ulcus duodeni) (Hentschel et al., 1991).

- 15 According to a study carried out by Forman et al. (Forman et al., 1993), an *H.pylori* infection leads to a 6 to 12-fold increase in the risk of developing some forms of gastric carcinoma (adenocarcinoma). The more rarely occurring MALT (mucosa associated lymphoid tissue) lymphomas of the stomach, which are regarded as
- being the precursors of B cell tumors of the immune system, are also suspected of being a consequence of infection with Helicobacter. In this regard, it has been demonstrated that Helicobacter heilmannii has a greater potential for causing cancer than does
- Helicobacter pylori and is causatively responsible for gastric MALT lymphoma (Stolte et al., 1997; Regimbeau et al., 1998). Providing appropriate patients with antibacterial treatment, involving the successful eradication (total elimination) of Helicobacter, leads
 - to both gastric ulcers and low-grade MALT lymphomas being healed (Sipponen and Hyvärinen, 1993; Isaacson and Spencer, 1993; Stolte and Eidt, 1993).
- Before the existence of $Helicobacter\ spec.$, and their importance for ulcer diseases, was known, these diseases were treated with antacids or H_2 receptor antagonists. The latter are substances which inhibit

the secretion of acid by the parietal cells of the stomach. The effect of these drugs is usually to cause the ulcers to heal; since, however, the drugs do not eliminate one of the causes of these ulcers, namely the infection with *Helicobacter*, the ulceration recurs (recidivation) after a short period of time in most cases.

Another therapy which is frequently employed association with ulcerations is that of 10 bismuth treatment. Various bismuth salts (CBS, BSS) have a bactericidal effect on Helicobacter. However, eradication of the organism is only achieved in 8-32% of cases. While the treatment apparently leads to a transient suppression of the organism, the infection 15 flares up again in most cases after the treatment has been discontinued. A more long-lasting therapy with high doses leads to an accumulation of the substance in the liver and kidneys and in the nervous system and has considerable neurological side effects (Malfertheiner, 20 1994).

Since it was realized that the gastroduodenal ulcer diseases were infectious diseases, an aim of 25 treatment has been that of eradicating the pathogens with antibiotics. However, monotherapy with various antibiotics (amoxycillin, tetracycline, nitrofuran, furazolidine, and erythromycin, inter alia) turned out to be unsatisfactory since, with these drugs too, the only eradicated in 0-15% 30 organisms are treatments. The previously recommended dual therapies using an acid blocker and an antibiotic also resulted in a high proportion of failures (Malfertheiner, 1994).

35 At present, the most successful treatment is achieved by the combination of an acid blocker (e.g. omeprazole) and two antibiotics in the form of the "French" triple therapy (amoxicillin and clarithromycin) or, in the

case of allergy to penicillin, the "Italian" triple (clarithromycin and metronidazole), therapy triple therapies can lead to eradication rates 80-95%. Because of its favorable properties. clarithromycin is increasingly becoming the agent of choice (Graham, 1995). A four-fold therapy (Proton pump inhibitor, bismuth salt, tetracycline and metronidazole or clarithromycin) is recommended in the therapeutic failure due to the bacteria being resistant 10 to clarithromycin or metronidazole, respectively. While this scheme promises success rates of about 95%, nevertheless also suffers from substantial side effects.

The antibiotic resistance status of the bacteria is an 15 important prerequisite for the success of the therapy. The failure rate of the treatment increases markedly as soon as there is resistance to only one of the two employed (Buckley antibiotics et al., 1997). The observation that the number of metronidazole-resistant 20 and clarithromycin-resistant H. pylori isolates been steadily increasing recently certainly gives cause for disquiet. While the reason for this is not known, it could lie in the increasing number of therapies for 25 eradicating H. pylori, in particular the dual therapies one antibiotic which have frequently implemented in the recent past and in which resistances frequently appear. Α resistance to macrolide antibiotics such as clarithromycin or erythromycin is 30 due to a point mutation in a particular region of the 23S rRNA. Such mutations apparently occur spontaneously and can readily be isolated by appropriate selection with an antibiotic. Rapid and reliable determination of the resistance status of Helicobacter isolates prior to 35 therapy is therefore of great importance for future.

35

The simplest method of detecting an acute Helicobacter infection with relative certainty is the so-called al., (Desroches et 1997). This breath test the decomposition of orally administered, measures $^{13}\text{C}/^{14}\text{C-labeled}$ urea into $^{13}\text{CO}_2$ or $^{14}\text{CO}_2$ and NH₄ by the 5 bacterial urease. The $^{13}CO_2$ or $^{14}CO_2$ reaches the lungs via the blood circulation and is released in the lungs by way of the natural gas exchange and consequently becomes measurable in the respiratory air. respiratory air is analyzed in a special appliance 10 which is only possessed by special laboratories, so that the results are often obtained at a different site from that at which the samples were taken and there is consequently a delay in receiving them. Other noninvasive methods are based on PCR reactions which 15 are carried out using stool or saliva samples (Schwarz et al., 1997). While these methods possess a very high degree of sensitivity, experience indicates that falsepositive results occur very frequently in routine operation. Furthermore, these methods require a basic 20 provision of apparatus and molecular biologicals which are not available in a general medical practice. This means that, in this case too, the samples have to be sent to special laboratories which means in turn that 25 there is no possibility of obtaining the results Indirect methods, which detect rapidly. Helicobacter antibodies in the serum or saliva, in turn suffer from the disadvantage that it is not possible to detect an acute infection beyond doubt.

As a rule, a gastroscopy is carried out when a positive breath test result has been obtained. A gastroscopy is often carried out in the case of a negative result as well, in particular when the symptoms do not subside after conventional therapy with proton blockers. As a rule, tissue samples are removed during a gastroscopy, in particular when it is possible to identify marked changes such as inflammations or ulcers. These tissue

15

20

25

examined histologically for benign samples are tissue changes. Microbiological malignant investigations, which are intended to assign organism unambiguously and to determine its minimum inhibitory concentration (MIC) value, are carried out, in particular. These results make it possible to plan a specific therapy and consequently guarantee a high degree of success. Inorder to perform microbiological investigations, it is necessary to culture the organism, a procedure which can take several days. After that, an MIC value determination is carried out, with this determination likewise being time-consuming and making it necessary to culture the organism. This investigation delays the beginning of the therapy substantially such that many dispense with this investigation, which is disadvantage of the patient. The consequence of this is that doses of antibiotic which are too high, and which are accompanied by massive side effects, are employed in a therapy. On the other hand, the dose of antibiotic employed can be too low because no detection of antibiotic-resistant organisms was carried out. A rapid and reliable identification of the organism which is possibly causing the disease, and the immediate determination of its resistant status, are therefore of the utmost importance.

Coccoid forms of *H.pylori* have been described in the literature on a number of occasions. However, the clinical importance of these stages is the subject of controversy. Some authors postulate that coccoid forms are a morphological manifestation of cell death and can no longer revert to the vegetative form (Kusters et al., 1997). Other groups assume that these bacteria are viable but non-culturable (VNC). Infection experiments carried out on various animal models have not been able to unambiguously clarify the question of whether it is possible to activate the coccoid form so as to convert

it into the vegetative form. Eaton and coworkers successfully infected minipigs with vegetative *H.pylori*, whereas coccoid forms did not give rise to any infection in this model (Eaton et al., 1995). By contrast, two independent research groups have reported successful infection with VNC *H.pylori* in the mouse model (Cellini et al., 1994; Wang et al., 1997).

Using stomach tissue sections obtained from biopsy 10 material, Chan et al. successfully detected coccoid forms directly in the human stomach. The authors were able to detect coccoid forms of H.pylori in 82.8% (53/64)of the biopsy samples examined using hematoxylin-eosin stain (Chan et al., 1994). Cao et al. used a monoclonal antibody for specifically detecting 15 coccoid H.pylori in the tissue section. In this case coccoid forms of H.pylori were detected, addition to the vegetative forms, in 100% of the antrum biopsies (9/9) (Cao et al. 1997).

20

that coccoid Other studies show forms can be induced preferentially by O_2 stress and by administering antibiotics (bismuth subcitrate, erythromycin, amoxicillin and metronidazole) (Donelli et al., 1998; Bode et al., 1993; Sorberg et al., 1996; 25 Berry et al., 1995), with polyphosphates evidently being used as an energy depot which could be sufficient for at least 3 months (Bode et al., 1993). Binding to epithelial cells and the ability to carry out signal 30 transduction (IL-8 induction, rearrangement of cytoskeleton, binding of plasminogen, lactoferrin and vitronectin on the bacterial surface) appear to be retained in the coccoid form at a level comparable to that in the vegetative forms (Khin et al., 1996; Segal 35 et al., 1996). It appears likely that the coccoid form is a survival form of Helicobacter.

invention relates to a novel process for determining, in microorganisms, in particular in bacteria, antibiotic reagents [sic] which are based on altered nucleic acid sequences, in particular ribosomal nucleic acids. 5 When use is made of hybridization probes which are specific for a nucleic acid sequence which is associated with antibiotic resistances, it is surprisingly possible, in the case of microorganisms from a biological sample, 10 rapid and reliable predictions about the presence and/or strength of an antibiotic resistance, or the minimum inhibitory concentration for an antibiotic, on basis of the appearance or absence hybridization in an in-situ detection method. The 15 present invention enables the attending physician to obtain results in an incomparably rapid and specific manner, thereby increasing the safety of the therapy for the patient and enabling the costs of the entire treatment to be reduced substantially.

Part of the subject-matter of the present invention is consequently a process for detecting antibiotic resistances in microorganisms, which process comprises the steps of:

- 25 a) preparing a sample which contains microorganisms,
 - b) bringing the sample into contact with at least one hybridization probe, which is specific for a nucleic acid sequence in microorganisms which is associated with antibiotic resistances, under conditions which permit the probe to hybridize specifically, and
 - c) analyzing the sample in situ by determining the appearance or absence of a hybridization.
- In a particularly preferred embodiment, several different hybridization probes are employed in the form of a mixture in the process according to the invention. Surprisingly, these different hybridization probes

bind, under identical hybridization conditions, to different target sequences with a specificity which is adequate for being able to detect a sequence difference of only one single base.

5

10

15

20

25

Preferably, the process according to the invention for detecting antibiotic resistances is used in bacterial nucleic acid organisms. The sequence which associated with antibiotic resistances is selected, in particular, from ribosomal nucleic acid sequences, particularly preferably from bacterial 23S ribosomal nucleic acid sequences. Particular preference is given using nucleic acid sequences peptidyltransferase center on the 23S RNA, the sequence which (for E.coli) is depicted in Particularly preferably, the selected nucleic sequence encompasses a region corresponding to one or more of the nucleotides 2032, 2057, 2058, 2059, 2503 on the E.coli 23S and 2611 rRNA (numbering accordance with Brosius et al., 1981), with mutations in particular, these positions relating, detecting resistances to macrolide antibiotics, e.g. clarithromycin and erythromycin. However, nucleic acid sequences from the 16S rRNA can also be detected, for example those nucleic acid sequences which mediate resistance to aminoglycoside antibiotics.

However, in addition to this, the process according to the invention is also suitable for detecting antibiotic resistances in other microorganisms, e.g. in protozoa. Organisms which particularly come into consideration in this regard are those which can be controlled by the administration of macrolide antibiotics, e.g. Giardia lamblia, a protozoan pathogen which is found in the upper small intestine in man and which is the causative agent of lamblia dysentery (Jablonowski et al., 1997), or Pneumocystis carinii, a protozoan organism which can

30

give rise to a pneumonia of frequently fatal outcome in immunodeficient patients, e.g. in HIV patients.

The process according to the invention has a number of advantages as compared with known methods for detecting antibiotic resistances. Thus, in contrast to classical biochemical detection methods, the process according to invention can also be used for rapidly investigating slowly growing pathogens or pathogens 10 which are difficult to culture, or cannot be cultured, in vitro. In addition to this, because the detection is is possible to locate the organisms in situ, it directly in affected areas of tissue. As compared with other molecular biological methods such as PCR, 15 process according to the invention is distinguished by the fact that time-consuming and labor-intensive DNA preparation methods are dispensed with and that the detection method is less sensitive to inhibitors which possibly be present in the sample material. 20 Furthermore, the nucleic acid which is detected can be associated with bacterial morphologies such as cocci, rods, etc., a feature which results in an improvement in the reliability of the process. It is also possible to locate and quantify the pathogen in affected areas.

The process according to the invention is more specific and sensitive than other microscopic methods, e.g. staining methods (Gram, Grocott-Gomori, Giemsa). As compared with immunofluorescence methods, the smaller size of the probe is an advantage, which probe allows better penetration into the tissue, scarcely exhibits any nonspecific binding and is universally applicable and associated with lower costs.

35 The process according to the invention is suitable for all microorganisms, in particular pathogenic bacteria such as streptococci, *Bordetella* and *Corynebacterium*, and, in particular, for problematic microorganisms such

WO 99/61660

as Helicobacter spec., e.g. Helicobacter heilmannii or mycobacteria, Porphyromonas pylori, Helicobacter acnes, Propionibacterium Borrelia gingivalis, burgdorferi, mycoplasmas, chlamydias and Tropheryma whippelii as well as representatives of the genera Bratonella, Legionella, Nocardia and Actinomyces, pathogenic organisms for other as Pneumocystis carinii and Giardia lamblia.

is 10 microorganism-containing sample prepared accordance with step (a) of the process according to the invention, preferably in the context of compiling results in human or veterinary medicine. While this sample can be any biological sample, it is preferably derived from human or animal tissues or body fluids, 15 tissue sections, biopsies or blood samples. Surprisingly, the process according to the invention has such a high specificity and sensitivity that the sample can be investigated without the microorganisms being previously cultured or multiplied. 20

Particular preference is given to a presumptive medium being added to the sample prior to the investigation. This presumptive medium is a medium whose composition is adapted to the microbial flora of the clinical 25 sample, in particular to the disease-causing organisms which may possibly be present, and conserves these organisms in a viable state for a limited period of time, e.g. from several hours to several days, but to a large extent suppresses growth of the organisms. Such a 30 presumptive medium essentially consists of a special nutrient solution which is present, where appropriate, in a semisolid organic matrix, e.g. an agar matrix (Westblom et al., 1991). The nutrient solution contains a nitrogen source and essential components, such as 35 trace elements, e.g. iron, zinc, manganese, vitamins, etc., which improve the stability of the of this organisms. All the other constituents

10

15

20

25

30

35

- 20 -

presumptive medium are preferably present in a buffered aqueous solution. The constituents of the nitrogen source are chemical or proteolytic digests of proteins of microbial, animal or vegetable origin, for example: peptones, tryptones or casitones or mixtures thereof, depending on the requirements of the selected microbial flora. In the case of anaerobic or microaerophilic organisms, reducing substances, such as reduced cysteine or thioglycolate, are admixed and/or oxygen-repelling additives are added to the medium.

Where appropriate, preparation of the sample can be additionally combined with an enrichment method, isolating organisms particular when from samples, e.g. blood or urine samples. The preferred enrichment method is based on binding the organisms to a solid matrix, in particular based on electrostatic interactions, e.g. to active charcoal or by way of defined ligands, such as polylysine, which are bound to a solid matrix. In accordance with the method, the blood flows, on withdrawal, into a sealed vessel, for example a syringe, which contains this matrix. After a brief incubation period, the blood is replaced by the abovementioned presumptive medium, with the matrixadsorbed organisms being conserved in a viable state in the sealed vessel.

Where appropriate, detection reagents, e.g. indicators which indicate the presence of pathogenic lead organisms within a short period of time, i.e. within minutes, can be added to the presumptive medium. This indicator can, for example, be a substrate mixture for a secreted lead enzyme (e.g. for the Helicobacter urease) whose conversion leads to a chromogenic product and/or indicates the production of characteristic substances such as particular toxins or metabolites.

Prior to being examined for antibiotic resistances, the sample is also preferably fixed, e.g. formaldehyde, paraformaldehyde or glutaraldehyde, and preferably permeabilized in order to hybridization probes to penetrate more efficiently into the cells. The permeabilization method is directed toward the pathogen which is in each case being investigated, with suitable permeabilization methods having to be used in each case for Gram-negative bacteria and Gram-positive bacteria.

The hybridization probes may be nucleic acids such as DNA or RNA or else nucleic acid analogues or combinations of these. Preference is given to the hybridization probes being selected from nucleic acids such as DNA or nucleic acid analogues such as peptide nucleic acids (PNA).

The hybridization probes possess a hybridization region 20 which is able to hybridize selectively with a target nucleic acid sequence in the microorganism. The length of this hybridization region preferably corresponds to from 10 to 30 nucleotide building blocks, particularly preferably from 15 to 20 nucleotide building blocks, in 25 particular from 17 to 18 nucleotide building blocks. The hybridization probes employed in the according to the invention are particularly suitable for detecting mutations, e.g. mutations of individual nucleotides or short nucleotide segments, which are 30 selected from deletions, transversions, transitions and modifications, e.g. methylations, of the corresponding wild type sequence.

The process according to the invention permits the use of a single hybridization probe. However, in many cases, it has proved advantageous to use a combination of several hybridization probes which are specific for different nucleic acid sequences associated with

antibiotic resistances. The probes ClaR1 (SEQ ID NO. 10, ClaR2 (SEQ ID NO. 2) and ClaR3 (SEQ ID NO. 3) are examples of hybridization probes according to the invention which can be used for detecting macrolide resistances at positions 2058 and 2059 of the 23S RNA. These probes can be used either singly or in combination.

In order to increase the sensitivity of the process according to the invention, the hybridization probes which are specific for mutations associated with antibiotic resistances can be used in combination with one or more hybridization probes which are specific for a nucleic acid sequence which is associated with the wild type of the microorganism (i.e. an antibiotic-sensitive strain). ClaWT (SEQ ID NO. 4), which can, for example, be used in combination with the previously mentioned probes ClaR1, ClaR2 and ClaR3, is an example of such a hybridization probe.

20

25

30

35

The ratio of resistant organisms to sensitive organisms in a sample can be determined by using wild type-specific probes and antibiotic resistances [sic] mutant-specific probes which each carry different labeling groups.

Furthermore, it is additionally possible to use, in the process according to the invention, a hybridization probe which is specific for a species or genus of microorganisms. Hybridization probes of this nature are known and are preferably directed specifically against ribosomal nucleic acid sequences, e.g. 23S RNA, 16S RNA or ribosomal spacer sequences. Examples of these probes are hybridization probes which are directed against sequences from H.pylori 16S rRNA which are homologous with the E.coli regions 110-140 and/or 740-780, in particular the hybridization probes Hpy-1-16S-753 (SEQ ID NO. 5) and 120b (SEQ ID NO. 6), 585 (SEQ ID NO. 7)

and 219 (SEQ ID NO. 8), which are used for the species-Helicobacter specific detection of pylori. of probes [lacuna] examples these which are specifically directed against sequences from H.heilmanii 16S rRNA which are homologous with the E.coli regions 580-610 and/or 640-670, in particular the hybridization probes Hh1 (SEQ ID NO. 9), Hh2 (SEQ ID NO. 10), Hh3 (SEQ ID NO. 11) and Hh4 (SEQ ID NO. 12) which are used for the species-specific detection of representatives of the H.heilmanii group.

- 23 -

species-specific probes can also be used detecting antibiotic-sensitive bacteria, in particular when using a probe mixture which contains, at one and the same time, probes for determining resistance and determining the respective species. combined probe mixture can be used, for example, for clarithromycin-resistant detecting Helicobacter bacteria (both the resistance probe and the speciesspecific probe bind) or other clarithromycin-resistant (the resistance-specific bacteria probe binds) antibiotic-sensitive Helicobacter bacteria (the resistance-specific probe does not bind the species-specific probe does bind).

25

30

35

10

15

20

Preference is given, in the process according to the invention, to using hybridization probes which carry a direct label, i.e. one or more labeling groups are linked directly to the probe, preferably by means of covalent bonding. On the other hand, it is also possible to use indirectly labeled or labelable probes, e.g. probes which carry a biotin group which is in turn detected by binding streptavadin, with the streptavadin being linked to suitable labeling а hybridization probes Alternatively, the can contain sequence regions which do not hybridize with nucleic acid sequences in the microorganism and which can be employed for hybridizing with a further, complementary, (directly or indirectly) labeled probe.

Any labeling groups per se can be used for the process according to the invention provided they enable the insitu detection to be sufficiently sensitive. Preference is given to dye groups, fluorescence groups and/or enzyme groups. Fluorescence labeling groups are particularly preferred.

10

15

20

25

30

35

If several types of hybridization probe (e.g. several mutation-specific probes or one or more mutationspecific probes in combination with wild type-specific probes and/or species-specific probes) are used in the process according to the invention, it may advantageous to employ different labeling groups, i.e. labeling groups which can be detected alongside each Thus, other. it is possible, for example additionally using species-specific probes which possess a label which is different from that of the mutation-specific probe, to obtain, when both hybridize at the same time, a third different color which results from the two probe colors being mixed. If, for example, a green fluorophore, e.g. fluorescein, is chosen for the probes for determining the bacterial species, and a red fluorophore, rhodamine, is chosen for the probes for determining antibiotic resistance, the mixture of the two colors is then yellow. Using this probe combination, it possible to determine the identity of the microorganism and the possible presence of an antibiotic resistance at one and the same time in one clinical sample. If the detected organism is antibiotic-sensitive, it can be reliably identified by the species-specific probe being bound on its own.

In addition to this, the process according to the invention even makes it possible to draw additional

conclusions with regard to the minimum inhibitory (MIC) of antibiotic-resistant concentration microorganisms. Thus, it has been found that particular point mutations, or particular combinations of point mutations, correlate directly with the MIC values determined by conventional means. MIC values therefore be determined by using hybridization probes which detect particular point mutations or particular combinations of these point mutations. For example, it is possible to use hybridization probes which are specially prepared for low, medium and high MIC values. This makes it possible for the attending physician to use precise doses of the antibiotic for the therapy.

The hybridization probe according to the invention is 15 specific for a nucleic acid sequence in microorganisms which is associated with antibiotic resistances. This means that hybridization conditions exist under which the hybridization probe hybridizes to a nucleic acid with is associated 20 sequence which resistances but not to a corresponding nucleic acid antibiotic-sensitive from wild sequence an organism. Depending on the base sequence the hybridization probe and the target sequence, the skilled person can readily, by means of empirical 25 hybridization ascertain conditions investigations, which are suitable for a particular test and which provide adequate specificity in distinguishing between wild type and mutated sequences. The hybridization buffer employed is preferably a buffer which contains 30 from 0.5 to 1.5 M salt, e.g. NaCl, a detergent, SDS and Washing preferably takes place formamide. formamide-free buffer. The probes are selected such that the hybridization temperature is preferably in the 35 range from 45 to 55°C.

The sample is evaluated in situ, preferably by microscopic methods, e.g. using a fluorescence microscope.

Another part of the subject-matter of the invention is in-situ nucleic acid hybridization the use of an for detecting antibiotic resistances process microorganisms, in particular in bacteria. The nucleic acid hybridization process is preferably carried out as previously described. The process is particularly 10 for detecting resistances to macrolide antibiotics. However, the process is also suitable for detecting antibiotic resistance mechanisms against lincosamide, aminoglycoside/aminocyclitol, tetracycline and chloramphenicol antibiotics and which 15 are based on changes in ribosomal RNA sequences.

Particular preference is given to detecting resistances macrolide antibiotics selected from the 20 consisting of clarithromycin, erythromycin, azithromycin and roxithromycin. In addition, particular preference is also given to detecting resistances to aminoglycoside antibiotics selected from the consisting of streptomycin, neomycin, paromomycin, 25 kanamycin, gentamicin, tobramycin, amikacin, netilmicin and sisomicin.

Yet another part of the subject-matter of the present invention is a reagent kit for typing microorganisms and/or detecting antibiotic resistances in microorganisms. In a first embodiment, this reagent kit is based on detection by in-situ hybridization and comprises:

- (a) means for preparing the sample, and
- 35 (b) at least one hybridization probe which is specific for a nucleic acid sequence in microorganisms which is associated with antibiotic resistances,

and/or at least one hybridization probe which is specific for a species or genus of microorganism.

The means for preparing the sample preferably comprise a presumptive medium which can have a composition as previously indicated. Alternatively, or in addition, the means for preparing the sample can also comprise means for enriching microorganisms, e.g. an adsorption matrix for enriching organisms from a liquid sample, 10 solutions or suspensions for fixing the sample, hybridization buffer and/or washing buffer. The preferably hybridization probes are labeled as previously described.

- 15 According to a second embodiment according to the invention, the reagent kit for typing microorganisms and/or detecting antibiotic resistances in microorganisms comprises
 - (a) a presumptive medium for microorganisms, and
- 20 (b) means for typing and/or detecting antibiotic resistances.

According to this embodiment, the means for typing and/or for detecting antibiotic resistances are not 25 restricted to using hybridization probes and other hybridization reagents. It is also possible to conceive of indicator substances which indicate the presence of microorganisms, e.g. urease detection reagents Helicobacter spec., e.g. H.heilmannii and/or H.pylori, hemolysin reagents for streptococci, and reagents for 30 detecting toxins produced by Clostridium difficile, Corynebacterium diphtheriae and Bordetella pertussis. is given to the reagents for microorganism species or genera already being dissolved 35 or suspended in the presumptive medium such that the contains a presumptive medium with combined indicator system. is also conceivable for Ιt presumptive medium with combined indicator system to be

additionally combined with an enrichment method. this case, the organisms are enriched from body fluids, for example blood, in a first step and treated, in a second step, with the indicator-containing presumptive medium. In addition, the kit can contain, appropriate in separate form, means for detecting antibiotic resistances, e.g. the previously described hybridization probes, and suitable buffers.

In addition to this, the invention relates to the use, 10 species-specific detection of Helicobacter the pylori and/or Helicobacter nemestriniae. oligonucleotide having a nucleotide sequence which is complementary to the 16S rRNA region of H.pylori which 15 corresponds to E.coli 16S rRNA positions 110 to 140 (in particular 120 to 137), 740 to 780 (in particular 753 to 770), 580-610 (in particular 585-605) or 210-245 (in particular 219-240). It was ascertained, surprisingly, that, when used as amplification primers 20 hybridization probes, such oligonucleotides, nucleic acids or nucleic acid analogues having a length of preferably from 10 to 30 nucleotide building blocks, exhibit a significantly higher specificity with regard to recognizing different H.pylori isolates than do 25 other sequences and, in addition to this, H. pylori and other related species to be differentiated reliably. Preference is given to using oligonucleotide which contains the sequences depicted in SEQ ID NO. 5, 6, 7 or 8 or at least a part region 30 thereof which is 10 nucleotides in length. In addition, the invention relates to the use, for specifically detecting representatives of the H.heilmannii group, of an oligonucleotide having a nucleotide sequence which is complementary to the 16S rRNA region of H.heilmannii 35 which corresponds to E.coli 16S rRNA positions 580-610 and/or 640-670. Preference is given to using oligonucleotide which contains the sequences depicted

in SEQ ID NO. 9, 10, 11 or 12 or a part region thereof which is at least 10 nucleotides in length.

oligonucleotide preferably carries a labeling The group. The species-specific substances can be employed on their own for identifying the organism. In addition, the species-specific probes can also be employed in combination with the detection of antibiotic resistances. Preference is also given to employing two or more species-specific probes in a test, with this 10 ensuring that less biologically active Helicobacter cells, which as a rule contain a lower number of ribosomes, are also detected.

- Yet another part of the subject-matter of the invention 15 is the use of an oligonucleotide from a bacterial 23S rRNA, in particular from a region which contains the peptidyltransferase center, for detecting antibiotic Preference is given resistances. to oligonucleotides which are specific for a mutation of 20 the wild type sequence which is associated with resistances and encompass antibiotic corresponding to one or more of the nucleotides 2032, 2057, 2058, 2059, 2503 and 2611 on the E.coli 23S rRNA.
- 25 Particular preference is given to oligonucleotides having the sequence depicted in SEQ ID NO. 1, SEQ ID NO. 2 or SEQ ID NO. 3. Where appropriate, these antibiotic resistance-specific oligonucleotides be used together with a wild type-specific 30 oligonucleotide which is directed against the region as is the resistance-specific probe. The wild type-specific oligonucleotide preferably has the sequence depicted in SEQ ID NO. 4.
- 35 Consequently, the present invention also relates to oligonucleotides, i.e. nucleic acids and/or nucleic acid analogues, which contain the sequence depicted in SEQ ID NO. 1, 2, 3, 4, 5, 6, 7, 8, 10, 11 or 12 or at

20

25

35

least a part region thereof which is 10 nucleotides in length. The invention also relates to compositions which contain two or more of said oligonucleotides. One or more of the oligonucleotides preferably carry a labeling group.

The invention is explained further by means of the following figures and examples.

10 diagram of the peptidyltransferase Fig. 1 shows a center in bacterial 23S rRNA. The diagram is a linear representation in which the positions at which resistance mutations have already been found are indicated by underlining. Filled the 15 circles represent footprints of erythromycin. The upper numbers relate to the helix numbering according to Brimacombe and the lower numbers relate to the nucleotide position in E.coli according to Brosius.

SEQ ID NO. 1-12 show the nucleotide sequences of the probes ClaR1 (1), ClaR2 (2), ClaR3 (3), ClaWT (4), Hpyl-165-753 [sic] (5), 120b (6), Hpyl-16S-585 (7) and Hpyl-16S-219 (8), Hh1 (9), Hh2 (10), Hh3 (11) and Hh4 (12).

Examples

30 Example 1

Developing a combination of *H. pylori*-specific and *H. heilmannii*-specific probes for the in-situ hybridization for detecting antibiotic-sensitive *Helicobacter* bacteria.

An alignment comprising 108 almost complete 16S rRNA sequences from organisms from the ϵ group of

10

15

20

proteobacteria (including 50 Helicobacter sequences, in turn including 10 H. pylori sequences) was used as a reference for deriving specific H. pylori probes (Neefs et al., 1993). This resulted in the assignment of a total of 4 potential target sequence regions, from which a variety of probe prototypes were derived for further testing. The testing of the different probe prototypes in an in-situ hybridization is an important element in the strategy for developing probes. Data are availabe which suggest that certain regions of the are not available for the ribosomal RNA hybridization reaction. Stable secondary structures and the occupation of probe-binding sites by ribosomal proteins have been discussed as possible causes for al, Frischer, 1995; 1996). this (Amann et particular, this testing has to be used to find the probe sequences which exclude the species which are most closely related to H. pylori, such as H. mustelae, H. fenneliae, C. coli, H. felis, C. jejuni W. succinogenes (see Table 5). The in-situ hybridization method employed in the testing described in detail in Example 2 below.

It was finally possible to determine, in each region, a 25 segment which was effective for probe construction, the probes Hpyl-16S-753, Hpyl-165-120b Hpyl-16S-585 and Hpy1-16S-219 being respectively located in these segments. Further extensive in-situ binding studies carried out on clinical samples showed 30 two probe sequences to be particularly effective: Hpyl-16S-585 and Hpyl-16S-219. Hpyl-16S-585 is directed against a region of the 16S rRNA sequence which only occurs in H. pylori and H. nemestrinae and is not found other bacterial species (Table 3). The probe 35 Hpyl-16S-219 is directed against another region which is specific for H. pylori. The two probes were provided either with the fluorescence dye fluorescein (emits green fluorescence) or the fluorescence dye Cy3 (emits

red fluorescence) by way of an amino linker at the 5' end. It is particularly important to use both probes simultaneously for detecting H. pylori in situ, in order to detect H. pylori cells which are metabolically less active. As a rule, bacteria whose metabolism is reduced have a lower content of ribosomes or rRNA, resulting in the detection method losing sensitivity, particularly when only one probe is used and this probe is provided with fluorescein, which is a dye which only emits comparatively weakly.

In addition, it was also possible to identify, from the 16S rRNA, the detection probes Hh1, Hh2, Hh3 and Hh4 which were specific for H. heilmannii (Table 3).

according to Brosius et al., 1981

For testing the probes, different reference cells were fixed with 3% buffered paraformaldehyde solution, as described in Amann et al., and immobilized on microscope slides by means of air drying (Amann et al., 1990).

5 ng of the probe are incubated with these microscope slides at 46°C for 90 min, in a hybridization buffer 10 (0.9 M NaCl, 0.02 M tris/HCl, pH 8.0, 0.01% SDS, 20% formamide). The slides are then washed for 15' at 48°C (0.25 M NaCl, 0.02 M tris/HCl, pH 8.0, 0.01% SDS). Excess washing buffer is removed from the microscope 15 slides with PBS and the slides are embedded Citifluor AF1 (Citifluor Ltd., London, UK) in order to decrease color-fading effects. The hybridization analyzed using an epifluorescence microscope (standard filters for red and green fluorescence). Under the 20 given conditions, all the H. pylori strains which have so far been tested (16/16) hybridized with the probe Hpy1-16S-753 whereas cells from other Helicobacter species and other reference strains (6/6) did not bind to the probe (Table 4). These other Helicobacter 25 species and further reference strains were the species which are most closely related to Helicobacter pylori, H.fennelliae, C. coli, H. mustelae, H. felis, C. jejuni and W. succinogenes (Table 4). Probe 120b reacted with 11 out of 16 strains and thereby displayed a somewhat lower specificity with regard to recognizing 30 different H. pylori isolates (Table 4).

Example 2

5

Using rRNA-directed, fluorescence-labeled oligonucleotide probes for the in-situ detection of 10 clarithromycin-resistant *H. pylori*.

Three different mutations in the 23S rRNA have by now been described which are able to mediate resistance to the macrolide clarithromycin (Versalovic et al., 1997).

15 According to the information in this article,

15

clarithromycin resistances can be caused by an $A \Rightarrow G$ in position 2058* (*nomenclature transition either according to Brosius) or 2059^* , or by an A \Rightarrow C transversion at position 2058*. In order to be able to detect all three resistance-mediating point mutations at one and the same time, three different probe sets were constructed, with these probe sets covering the abovementioned region in different ways. In view of the special requirements of an in-situ hybridization, the in-situ binding properties of the different probe sets were tested in a manner analogous to that used for the H. pylori-specific probes (see Example 1). The crucial selection criteria were as follows: (1) unambiguous each respective point detection of mutation, simultaneous detection of the point mutation and of the H. pylori-specific rRNA segments by simultaneously using the probes identified in Example 1.

It was finally possible to identify three probes which were effective for detecting the three resistance-20 mediating mutations in situ: ClaR1, ClaR2 and ClaR3. The probes ClaR3 and ClaR3. [sic] The probes ClaR1 and ClaR3 are complementary to the rRNA which is altered at position 2058*, whereas probe ClaR2 is complementary to 25 the rRNA which is mutated at position 2059*. The probes were provided either with the fluorescence dve fluorescein (emits green fluorescence) or with the fluorescence dye Cy3 (emits red fluorescence) by way of an amino linker at the 5' end. It is advantageous to 30 label the probes with the more strongly fluorescence dye Cy3 since this ensures more sensitive detection, particularly when the cells are H. pylori cells which are metabolically less active (see above).

35 The above-described probes were used to test suitable conditions and finally verify them on a total of 20 clarithromycin-resistant and 15 clarithromycin-sensitive *H. pylori* strains. It was possible to

demonstrate unambiguously that the resistance detection was specific for *H. pylori*, since the two probes H.pyl-16S-219 and Hpyl-16S-585 reacted with all the *H. pylori* strains examined, whereas none of the related Helicobacter species was detected. ClaR1 recognizes the mutation A2058G (Cla^R), ClaR2 recognizes the mutation A2059G (Cla^R) and ClaR3 recognizes the mutation A2058C (Cla^R).

10 A resistance determination should preferably be carried out using all five probes (ClaR1-3; Hpyl-16S-585; Hpyl-16S-219), since this achieves optimum analytical power In this embodiment, it below). has proved advantageous to detect the point mutations competitive hybridization assay and in this way ensure 15 that this detection is specific. To this end, a probe was additionally admixed with the probe mixture, with this probe being complementary to the wild sequence in the region of the resistance-mediating 20 mutations. The sequence of the probe ClaWT ascertained after appropriate tests. The three Cv3labeled probes ClaR1, ClaR2 and ClaR3 are used together with an equimolar quantity of the unlabeled ClaWT probe. In order, at the same time, to indicate the 25 identity of the bacteria which are present, the two FLUOS-labeled H. pylori-specific probes are used addition. The following conclusions can therefore be

H. pylori strains were detected in one biopsy sample, i.e. a clarithromycin-resistant strain and a clarithromycin-sensitive strain.

Example 3

20

Determining the clarithromycin resistance of *H. pylori* in situ in tissue sections.

possibility of determining the resistance H. pylori in situ in tissue sections was first of all evaluated in an animal model. 6-8-week-old C57B16 mice were infected orally with 10 colony-forming units of the H. pylori strain P76. The mouse was killed 4 days 5 after the infection and the stomach was removed under sterile conditions. The stomach was chopped into small pieces with a scalpel and the pieces were placed in a 3% solution of paraformaldehyde for 12 h. This was then followed by two washing steps, of one hour in each 10 case, in a buffered salt solution, e.g. PBS. material was then placed in a frozen section medium, after which it was all frozen at -70°C. Finally, frozen sections, which were each 5-10 µm in thickness, were prepared from the frozen material using a cryomicrotome 15 fixed on polylysine-coated microscope slides. Carrying out the detection reaction in accordance with the above-described conditions then gave a positive result, such that it was possible to clearly detect the individual H. pylori organisms on the inner side of the 20 crypt in the stomach sample.

In continuing the investigation, use was now made of paraffin sections of stomach biopsies taken 25 chronically infected humans whose microbiological determined beforehand background had been conventional methods. The tissue sections were examined in accordance with the standard protocol, with the two FLUOS-labeled H. pylori-specific probes, the 30 labeled probes ClaR1, ClaR2 and ClaR3, and unlabeled ClaWT probe all being employed. A total of 27 stomach biopsy samples was examined, with an H. pylori infection being diagnosed correctly, i.e. in agreement the conventional method, in 17 cases. A clarithromycin resistance was detected correctly in 5 35 cases. A mixed infection of H. pylori, consisting of clarithromycin-resistant strain and clarithromycinsensitive strain, was even detected in one case (see Table 5).

In another application form, the stomach biopsies are not fixed and worked up histologically; instead, they are transferred into a special transportation and/or presumptive medium which ensures that the organism survives over a long period and indicates the presence of *H. pylori* in the sample, where appropriate 10 Example 5). Ιf samples are removed from the transportation medium after storage times of differing lengths and examined using the above-described process, it is surprisingly still possible to characterize the bacteria unambiguously after 7 days. The finding that the sample did not necessarily have to be stored in the 15 cold (4°C) for this was particularly surprising.

Example 4

Comparing the 23S rRNA sequences of different medically important bacteria within the clarithromycin resistance region.

5

10

15

20

25

(Ludwig al., computer program ARB et Technical University) was used to compare the 23S rRNA from 40 Gram-positive and Gram-negative bacteria with the macrolide resistance-mediating region of H. pylori (Table 6). In all the bacteria examined, the results show strong conservation of the primary structure of this special region of the ribosomal RNA resistance to macrolide antibiotics is determined. the binding specificity of the identified However, probes ClaR1, ClaR2 and ClaR3 for H. pylori appears to be met. Since the 40 sequences from the database are clarithromycin-sensitive from probably sequences bacteria, and it can be assumed that clarithromycin resistance in these bacteria, as in H. pylori, is also determined by a mutation in positions 2058/2059 of the 23S rRNA (in accordance with Brosius), the abovedescribed process for determining macrolide resistances in situ can also be employed in the case of these bacteria. Ιt is only necessary, for unambiguously classifying the corresponding pathogenic organism which linked to the pathogenic process, to derive a species-specific probe and to combine this probe, the manner described, with the probe mixture for identifying the resistance-mediating mutation.

mis, number of mismatches with the rRNA sequence in this region. The starting position of the probe sequence in the 23S rRNA of the different species corresponds to position 2051 in E. coli (Brosius et al., 1981), N, corresponds to A, C, G or T. = identical to the rRNA sequence.

Example 5

5

Developing a presumptive medium for bacterial gastritis
10 combined with urease detection especially for
Helicobacter pylori

The particular aim is to develop a presumptive medium which should make it possible to conserve viable Helicobacter pylori bacteria from stomach biopsies, 15 ideally over a period of 5 days but at least over In addition, the accompanying flora, 48 hours. present, should be preserved in order to ensure that the microbiological evaluation is complete. The growth of the organisms must be restricted in order to keep 20 the fractional composition of the organisms in the biopsy as unaltered as possible. The presumptive medium essentially consists of a buffered nutrient solution which is preferably present in a semisolid organic matrix, such as (0.2-1.5%) agar or (at least 15%) 25 gelatin. The nutrient solution contains a nitrogen source and further essential components which improve the stability of Helicobacter. The nitrogen takes up from 0.5 to 5% of the presumptive medium. It consists of chemical or proteolytic digests of proteins 30 of microbial, animal or plant origin, such as peptones, tryptones or casitones or mixtures of these compounds. Particular preference is given to media such as Schivo-Medium® or brain-heart infusion (BHI)-based media. Other preferred constituents are yeast extract (e.g. 35 0.01%), serum proteins, such as horse serum or fetal calf serum or bovine serum albumin, and defined organic substances, such as 2,6-dimethyl-beta-cyclodextrin and

cholesterol. The serum proteins should take up 1-10% of the presumptive medium, with the organic substances taking up 0.01-0.2%. In addition, reduced cysteine or thioglycolate are admixed with the presumptive medium and/or oxygen-repelling additives are added to it. All the components are present in a buffered, aqueous solution whose preferred pH is between 5.5 and 6.5. The biopsy sample is introduced into the lower third of the semisolid matrix thereby preventing atmospheric oxygen from diffusing in, an arrangement which improves the survival conditions for the organism.

presumptive medium with Combining the а detection test is novel. It offers the physician the 15 advantage that he is given a rapid indication of a infection and possible Helicobacter can directly initiate further measures. To this end, (0.5-5%) urea and (0.001-0.01%) phenol red, or other pH indicators, such a bromcresol purple, are also added to 20 presumptive medium. The transformation of the urea by urease leads, inter alia, to the production of ammonia, which makes the pH basic and, for example, changes the pH indicator phenol red from yellowish into red to violet. The speed of the color change, the intensity of 25 the color, and the coloration, correlate directly with quantity of urease-producing bacteria. The constituents of the combined presumptive medium are adjusted such that high sensitivity is (500-2000 organisms/presumptive medium) and autolysis 30 of the organisms is suppressed. Alternatively, synthetic urease substrate, whose transformation brings about a color change, can be admixed with presumptive medium.

Comparative investigations provide evidence that other, routinely employed urease detection methods lead to rapid lysis of the organisms. This is of the greatest importance since more recent investigations show that

10

15

20

25

other urease-producing organisms, such as Proteus Klebsiella oxytoca and Pseudomonas mirabilis, aeruginosa, are frequently to be found in the biopsy samples. In contrast to Helicobacter, these organisms do not secrete any urease; instead the enzyme is present inside the cell. In our own investigations, we have established that the bacteria are lysed in current urease detection methods such as the CLO test, with the intracellular urease being released and immediately reacting with the substrate which is now available. In a provisional investigation carried out on 32 patients suffering from acute gastritis, it was only possible, when conventional methods were used, to isolate a Helicobacter from 34% of the biopsies which were examined microbiologically. In this connection, possibility cannot be ruled out that the Helicobacterfree biopsies were colonized with strains which are very difficult to culture. However, it is significant that a major part (> 50%) of the Helicobacter-free biopsies contained other urease-producing organisms which were detected by the currently employed methods for detecting urease. The combined transportation and indicator medium delays or prevents lysis of these bacteria and consequently guarantees that the detection of urease is Helicobacter-specific.

Table 8:

Urease-producing organism1	Change in color medium ²	of the presumptive		
	5 hours	24 hours		
Helicobacter pylori	++ (< 10 minutes)	+++		
Proteus mirabilis	+/- (> 3 hours)	++		
Klebsiella oxytoca	_	_		
Pseudomonas		_		
aeruginosa				

- One complete bacterial colony was used for each test.
- The presumptive medium was incubated at room temperature (21-25°C) and evaluated visually.

Example 6

Testing clarithromycin-resistant H. pylori strains for antibiotic sensitivity by means of in situ detection with rRNA-directed fluorescence-labeled probes.

10

15

Based on the observation made by Versalovic et al. (1997) that the different resistance-mediating point mutations on the 23S rRNA correlate with the sensitivity of the organism to clarithromycin, the possibility arises, from the present, novel results, of directly testing for antibiotic sensitivity by using the individual probes (ClaR1-3).

mutations in position A2058G lead Thus. 20 significantly higher resistance values than mutations in position A2059G. As has previously been demonstrated, the probe ClaR1 detects the mutation in position A2058G specifically. In an optimization process, highly specific detection of the A2058G point 25 mutation was achieved with a mixture consisting of the Cy3-labeled ClaR1 probe and the unlabeled probes ClaWt and ClaR3.

A functional probe mixture for specifically detecting the A2059G point mutation, and consisting of the Cy3-labeled ClaR2 probe and the unlabeled ClaWT probe, was developed in a similar manner. The Cy3-labeled probe Cla3 is used in combination with the unlabeled probe ClaWT for detecting the point mutation A2058C.

. 35

The hybridization is carried out in the buffer mentioned in Example 2. If the test for antibiotic sensitivity is to be coupled with the identification of

H. pylori, the FLUOS-labeled oligonucleotides Hpyl-16S-585-FLUOS and Hpyl-16S-219-FLUOS are then also added to the abovementioned probe combinations.

Table 8:

5 Evaluating the MIC value determination by in-situ hybridization using conventionally characterized *H. pylori* isolates.

Species	Strain	ClaR1	ClaR2	ClaR3	Hpyl-16S-	MIC value

	MC132	_	+	-	+	12	

- no fluorescence signal detectable.
- 10 + clear fluorescence signal detected

Example 7

The overall process for determining resistance is composed of two successive constituent steps, i.e. the isolation of the sample (A) and the detection reaction (B).

Sample isolation essentially comprises specifically isolating biological material which has been colonized by the disease-causing organism. The biological material which has been obtained can then be directly supplied to the detection reaction, or fixed using known methods, or transferred into a special presumptive medium (see Example 5).

WO 99/61660

5

The detection reaction (in situ hybridization) essentially requires three procedural steps, i.e. (1) immobilization of the sample on a support, (2) permeabilization of the sample, and (3) the actual hybridization reaction and its evaluation.

In the case of microscopic examination, the sample is immobilized on a microscope slide which is as a rule made of glass. It is also possible to use other support materials, e.g. microtiter plates or films or silicon 10 plates depending on the form of investigation selected. As a rule, the sample is applied to the microscope slide in the form of a smear. In the case of tissue samples, preference is given to usina Finally, the sample is immobilized on the microscope 15 slide by means of air drying (Amann et al., 1990), with it being possible to improve the fixing of the sample pretreating the microscope slide, e.g. polylysine or even specific receptor molecules such as 20 antibodies.

permeabilization step makes the sample, in particular the bacteria which are present in the sample, permeable to the probes. The process is 25 designed such that it is in particular the bacterial which is made permeable, with the internal structure being to a large extent preserved. As a rule, conventionally implemented fixing method sufficient for permeabilizing Gram-negative bacteria. 30 The permeabilization of Gram-positive bacteria requires additional measures, e.g. using components organic solvents, for example toluene, xylene, acetone, ethanol, etc., detergents, for example SDS, Nonidet, etc., and cell wall-decomposing enzymes, for example 35 lysozyme, lysostaphin, mutanolysin, etc.

The hybridization reaction is carried out in two steps, i.e. (a) incubation of the permeabilized sample with

the labeled probe or the probe mixture, and (b) a subsequent washing step for removing non-specifically probes, with this being followed by evaluation. The probes (1-1000 ng) are incubated in an aqueous solution for several hours at a temperature 5 which can be derived from the formula for calculating the dissociation temperature of RNA/DNA hybrids (Lathe, 1985; Wahl et al., 1987): $Td = 81.5 + 16.6 Ig[Na^{\dagger}] =$ 0.4(%GC) - 820/n - 0.5(%FA); n =length of the 10 oligonucleotide; FA = formamide. The essential components of the aqueous solution are chaotropic salts and/or formamide, substances, such as specific binding of the probes ensure complementary target sequences on rRNA, and a detergent for suppressing nonspecific binding of the probes, e.g. 15 to proteins. In principle, the solution for washing out nonspecifically bound probes has a composition, with the constituents which affect the binding of the probes being employed in lower 20 concentrations and/or the temperature being correspondingly increased. Finally, the excess washing buffer is removed from the microscope slides with a buffered salt solution, e.g. PBS, and the sample region is embedded in Citifluor AF1 (Citifluor Ltd., London, 25 UK) in order to decrease fading of the fluorescent probes during the investigation. The result of the detection reaction is read off using a fluorescence (standard filter for microscope red and areen combined filter fluorescence and/or a for 30 simultaneously detecting red and green fluorescence).

Example 8

It has been observed that, under unfavorable living conditions, *H. pylori* changes its morphology and converts itself from the known rod form into a coccoid form. It is known that this coccoid form can no longer be cultured and is consequently not accessible to

classical microbiological investigations. If these forms are indeed survival stages of *H. pylori*, it has to be possible to diagnose them.

5 A series of experiments was carried out in order to examine to what extent the coccoid forms are available the above-described detection process determining antibiotic resistance. A clarithromycinresistant H. pylori strain was converted coccoid form by storing it in distilled water for one 10 week at 4°C. After this period of time, all the rodshaped H. pylori cells had been completely transformed longer coccoid forms, which no grew conventional culture media. These coccoid cells were subjected to the above-described detection process 15 using the known probe mixture. Success was in fact achieved in identifying the coccoid form as being something which H. pylori and, is particularly important, clarithromycin-resistance was detected as 20 well. Since then, the above-described process has even been used to successfully detect these forms in human tissue biopsies.

This is, therefore, the first detection method which is 25 available for determining resistance to an antibiotic in coccoid Helicobacter. In addition to this, it was not to be expected that this method would function in coccoid H. pylori. There have been many reports in the literature that the coccoid form has a greatly reduced 30 content of rRNA and that, furthermore, this rRNA is degraded (Donelli et al., 1998; Narikawa et al., 1997). Our investigations prove that the coccoid form which is induced in H2O has a content of rRNA which sufficient to be detected, and can be very readily characterized by an in-situ hybridization which is 35 directed toward the rRNA.

coccoid forms assumes Investigating greater particularly connection significance in with determining resistance. It is known that coccoid forms preferentially arise in association with sublethal antibiotic concentrations and that these forms are therefore possibly connected with failures in antibiotic therapy. In addition to this, it is probable that these forms occur at high concentrations in the stools of infected patients and that the described process can therefore be used to detect an infection with a clarithromycinacute H. pylori resistant organism simply and rapidly, i.e. without the gastroendoscopic removal of a biopsy sample.
